NCRM Research Methods Festival
3 July, 2008

Overview

Review of statistical methods for combining population and survey data – with some applications

- ▶ Examples of population and survey data, (dis/)advantages of each
- ▶ Combining data in **estimation** problems:
 - ▶ Small area estimation
 - ▶ Reweighting surveys to population.
- ▶ Determining **associations** between variables
 - ▶ Reducing ecological bias from aggregate data using individual data.
 - ▶ Combining datasets with different sets of variables.
- ▶ Running theme: multilevel and Bayesian **graphical models**

Definitions

Examples of **population data** – nominally represents everyone

- ▶ the census area-level data (at various levels of aggregation)
- ▶ national registers of births and deaths
- ▶ case registers for specific diseases (cancer, congenital anomalies)

Definitions

Examples of **population data** – nominally represents everyone

- ▶ the census area-level data (at various levels of aggregation)
- ▶ national registers of births and deaths
- ▶ case registers for specific diseases (cancer, congenital anomalies)

Examples of **survey data** – subset of population

- ▶ Annual Population Survey, Health Survey for England
- ▶ British Household Panel Survey, Millennium Cohort Study (longitudinal)
- ▶ Samples of Anonymised Records from the Census

Characteristics of population data

Advantages of censuses and registers:

- ▶ **Representative** of population (nominally, although may be small selection effects / under-enumeration).
- ▶ **Large** – statistical power to discern small effects

Characteristics of population data

Advantages of censuses and registers:

- ▶ **Representative** of population (nominally, although may be small selection effects / under-enumeration).
- ▶ **Large** – statistical power to discern small effects

Disadvantages:

- ▶ Limited number of variables beyond basic demographics
 - ▶ especially in registers. Census better but limited information on e.g. health
- ▶ Often available only as **aggregate** counts / percentages over areas – loses potentially important information (see later)
- ▶ ... **access** to most detailed form of data usually restricted.

Characteristics of survey data

Advantages:

- ▶ Individuals can be examined in detail on a particular research area (e.g. Health Survey for England - different health topic every year)
 - ▶ lots of variables collected

Characteristics of survey data

Advantages:

- ▶ Individuals can be examined in detail on a particular research area (e.g. Health Survey for England - different health topic every year)
 - ▶ lots of variables collected

Disadvantages:

- ▶ Small subset of the population
 - ▶ limited information on geographical variations
 - ▶ limited power to detect small effects e.g. environmental exposures
- ▶ Often selection bias by design, as well as biased non-response
 - ▶ may need to reweight to represent population

Combining population and survey data

- ▶ One dataset presents only one piece of the picture
- ▶ Make most of information from different sources
- ▶ Improves **power** and can alleviate particular **biases**:
 - ▶ selection bias, confounding, ecological bias, missing data, measurement error
- ▶ ... May require complex models to represent complex situations
 - ▶ data must be available to inform about particular biases

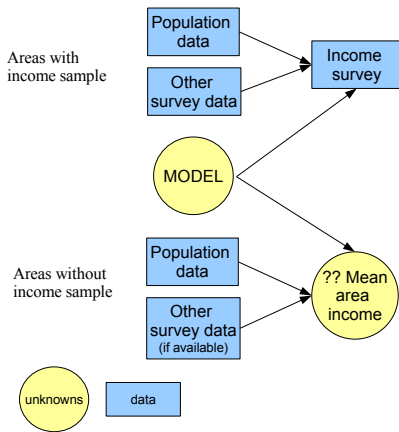

Combining population and survey data

- ▶ One dataset presents only one piece of the picture
- ▶ Make most of information from different sources
- ▶ Improves **power** and can alleviate particular **biases**:
 - ▶ selection bias, confounding, ecological bias, missing data, measurement error
- ▶ ... May require complex models to represent complex situations
 - ▶ data must be available to inform about particular biases

Consider research questions of the form:

- ▶ **estimating** quantities (*“what’s the mean income among (ethnic group) in (area)”*), or
- ▶ finding **associations** between quantities (*“how is income related to chronic illness”*)...

Small area estimation

- ▶ no population income data
- ▶ but surveyed data not available for all areas / too few responses
- ▶ Principle: fit a model to surveyed data
 - ▶ model based on association between population data / other surveyed data and income
 - ▶ may also exploit correlation between neighbouring areas (Bayesian hierarchical models, see Spatial Statistics session this afternoon)
- ▶ → use model to predict income for other areas.

Accounting for survey selection bias

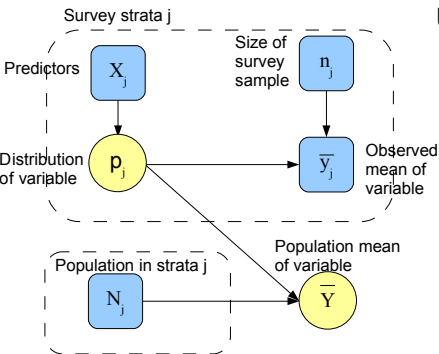

- ▶ Estimating quantity of interest for a population from survey data y_1, \dots, y_n
- ▶ Mean of surveyed variable $\sum_i y_i/n$ is biased due to selection.
- ▶ **Reweight** survey responses to represent population:
 $\bar{y} = \sum_i w_i y_i/n$, where $w_i = 1/\text{probability of selection}$.
- ▶ Weights w_i may be known from sampling design
 - ▶ but what if design not published,
 - ▶ or certain individuals decline invitation to survey,
 - ▶ or “item” non-response to some survey questions ...?

Poststratification for selection bias

Poststratification: compare survey data with **population data** to estimate probabilities of selection:

- ▶ Define a set of strata r (e.g. sex \times age \times socio-economic)
- ▶ n_r responses in each r from a population of N_r .
- ▶ \rightarrow probability of selection = n_r/N_r for stratum r
- ▶ Or improve precision further using a **model** for the variable of interest. . .

Model-based poststratification for selection bias

Using a **model** for the variable of interest

- ▶ Distribution p_j of variable within stratum j estimated from **survey** data
- ▶ modelled in terms of predictors *in addition to* strata, or **smoothed**,
 - ▶ exploiting correlations between similar strata / correlations through time in, e.g. annual surveys
- ▶ → compute population mean of variable of interest using p_j and **population** N_j

See, e.g. Gelman and Carlin, *Poststratification and weighting adjustments*, Survey Nonresponse, 2002. (with examples from US political opinion polls)

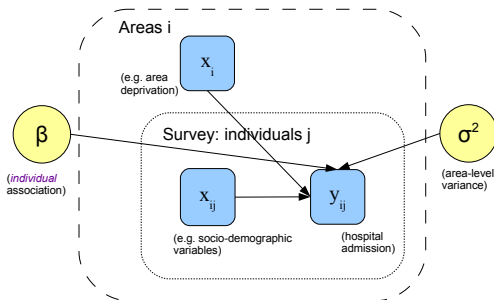

Association problems

Or “*regression*” or “*correlation*” problems.

Examples:

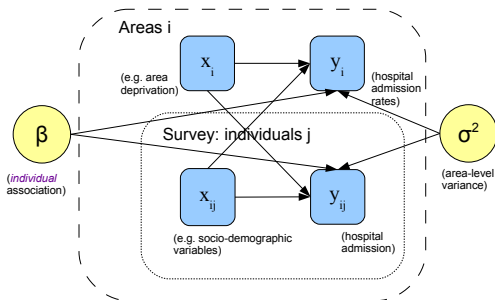

- ▶ effects of environmental exposure / socio-economic status on incidence of a disease.
- ▶ Contrasting **individual** and **contextual** effects on health:
 - ▶ do characteristics of your neighbours / area determine (e.g.) your health, as well as your own characteristics
 - ▶ needs individual and area-level data – often population and survey data

Multilevel models for individual / contextual effects

- ▶ Individual outcome: hospital admission for CVD (from Health Survey for England).
- ▶ Modelled on **individual** and **area-level** socio-demographic predictors.
- ▶ **Multilevel model** separates individual / area variations in outcome
 - ▶ account for correlations within areas

Multilevel models for individual / contextual effects

- ▶ What if we also have **area-level outcomes** as well as individual-level outcomes?
- ▶ e.g. hospital admissions data: proportion admitted to hospital for CVD.
- ▶ Estimate predictors of **individual-level** hospital admission simultaneously from area / individual data ...

Ecological inference

Estimating individual-level associations from area-level averages – prone to **ecological bias** (= ecological fallacy):

1. association is different for area-averaged data (for non-linear individual models e.g. binary and count data)
2. can't distinguish between individual / area exposure effect

Ecological inference

Estimating individual-level associations from area-level averages – prone to **ecological bias** (= ecological fallacy):

1. association is different for area-averaged data (for non-linear individual models e.g. binary and count data)
2. can't distinguish between individual / area exposure effect

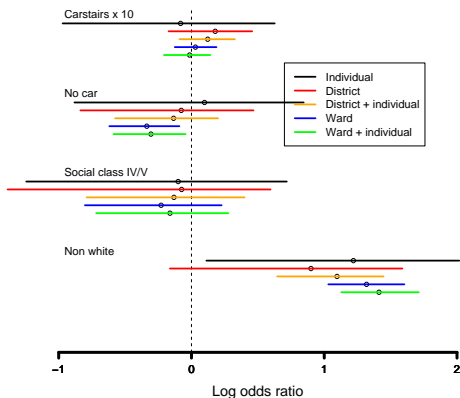

Solutions:

1. use appropriate models (see, e.g. Wakefield, J Roy Stat Soc A, 2004)
 - ▶ instead of simple regression of area outcome on area exposure
 - ▶ computes appropriate **area-level risk** as individual risk averaged over **within-area** distribution of risk factors.
 - ▶ needs an estimate of within-area exposure distribution. . .
2. incorporate **individual-level data** – improves power, and . . .

Using individual data to alleviate ecological bias

- ▶ Individual **exposure** data alone – improves estimate of within-area variability
 - ▶ (Best et al., Environmental benzene exposure and childhood leukaemia. J Roy Stat Soc A 2001)
- ▶ Individual **exposure-outcome** data – direct information on association of interest (*hierarchical related regression*)
 - ▶ (Jackson, Best and Richardson, Stat Med 2006, J Roy Stat Soc A 2008, also see <http://www.bias-project.org.uk/research>)
- ▶ **Case-control data** – outcome-dependent sampling – more informative than survey data when outcome is **rare**
 - ▶ (Haneuse and Wakefield, J Roy Stat Soc B, 2008)

Socio-demographic predictors of CVD hospitalisation

(risk of hospital admission for CVD in 1998 for adults in London. Jackson, Best and Richardson, J Roy Stat Soc A, 2008)

- ▶ Estimates from individual data / district data not precise
- ▶ Combining individual and aggregate data increases power.
- ▶ Using smaller areas (wards instead of districts) improves precision further.
- ▶ No additional effect of area-level deprivation (Carstairs index) on top of individual factors

Graphical model for combining mismatched data

Births with complete data (survey)

- ▶ Study of relationship of low birth weight to environmental pollution
- ▶ Millennium Cohort Study: about 20,000 UK births in year beginning Sep 2000.

Graphical model for combining mismatched data

Births with complete data (survey)

- ▶ Study of relationship of low birth weight to environmental pollution
- ▶ Millennium Cohort Study: about 20,000 UK births in year beginning Sep 2000.
- ▶ Relationship confounded by ethnicity and smoking

Graphical model for combining mismatched data

Births with complete data (survey)

- ▶ Study of relationship of low birth weight to environmental pollution
- ▶ Millennium Cohort Study: about 20,000 UK births in year beginning Sep 2000.
- ▶ Relationship confounded by ethnicity and smoking
- ▶ Survey may not have power to detect small association with pollution

Graphical model for combining mismatched data

Births with complete data (survey)

- ▶ Study of relationship of low birth weight to environmental pollution
- ▶ Millennium Cohort Study: about 20,000 UK births in year beginning Sep 2000.
- ▶ Relationship confounded by ethnicity and smoking
- ▶ Survey may not have power to detect small association with pollution
 - ▶ Incorporate population data

Graphical model for combining mismatched data

Births with complete data (survey)

Births with missing confounders (population register)

- ▶ National births register – all births in population
- ▶ Important confounders – smoking and ethnicity – not recorded

Graphical model for combining mismatched data

Births with complete data (survey)

Births with missing confounders (population register)

- ▶ Fit model for confounders using data from survey
 - ▶ based on predictors **available in both datasets**, including pollution.

Graphical model for combining mismatched data

Births with complete data (survey)

Effect on confounder

Effect on outcome

Births with missing confounders (population register)

- ▶ Fit model for confounders using data from survey
 - ▶ based on predictors **available in both datasets**, including pollution.
- ▶ Predict from that model to impute confounders in register
 - ▶ = standard multiple imputation for missing data

Graphical model for combining mismatched data

Data	Odds ratio (95% CI) for IQR of NO ₂ exposure
Millennium Cohort data alone	0.94 (0.79, 1.13)
Register data (ignoring confounders)	1.15 (1.07, 1.23)
Combined data	0.98 (0.91, 1.04)

(Jackson, Best and Richardson, 2008, Submitted to *Biostatistics*. See <http://www.bias-project.org.uk/research>)

- ▶ Power increased by combining data
- ▶ Confounding appropriately controlled for
 - ▶ ... but needs sufficient predictors of missing data
 - ▶ here we used area-level ethnicity from census
- ▶ **Bayesian graphical model** used to propagate **uncertainty** about imputation ...

Bayesian graphical models

- ▶ Generalisation of multilevel models (hierarchical relationships) to any network of quantities.
- ▶ Complex system represented as global model built from smaller components
 - ▶ each representing different data source or bias
- ▶ Nice mathematical properties – network structure exploited to form joint probability distribution of unknowns
- ▶ Efficient algorithms (Markov Chain Monte Carlo) used to estimate distribution of unknowns given data – exploiting network structure → general-purpose software e.g. WinBUGS

Summary: combining population and survey data

- ▶ Observational data prone to **biases** (selection, confounding, missing data ...) – multiple data sources can inform and alleviate biases
- ▶ Combining suitable data can **improve power** – each dataset presents a small part of the picture.
- ▶ Statistical methods like **graphical models** useful
 - ▶ complex → need to check model assumptions
 - ▶ better to have tidier data in first place...?
- ▶ Data of different forms from the **same source** particularly valuable – e.g. Samples of Anonymised Records / population aggregate data from the census.
